# *Designing a PRNG*

---

We have seen in the last lecture one way how *not* to do it:  
Linear Congruential Random Number Generators (LCPRNGs).

# *Designing a PRNG*

---

We have seen in the last lecture one way how *not* to do it:  
Linear Congruential Random Number Generators (LCPRNGs).

We will show you how to design a *practically strong* RNG.

# Designing a PRNG

---

We have seen in the last lecture one way how *not* to do it: Linear Congruential Random Number Generators (LCPRNGs).

We will show you how to design a *practically strong* RNG.

A RNG is *practically strong* if it cannot be predicted *in practice*. There might be *theoretical* attacks on the generator, but if they are not also *practical*, they are disregarded.

# Designing a PRNG

---

We have seen in the last lecture one way how *not* to do it: Linear Congruential Random Number Generators (LCPRNGs).

We will show you how to design a *practically strong* RNG.

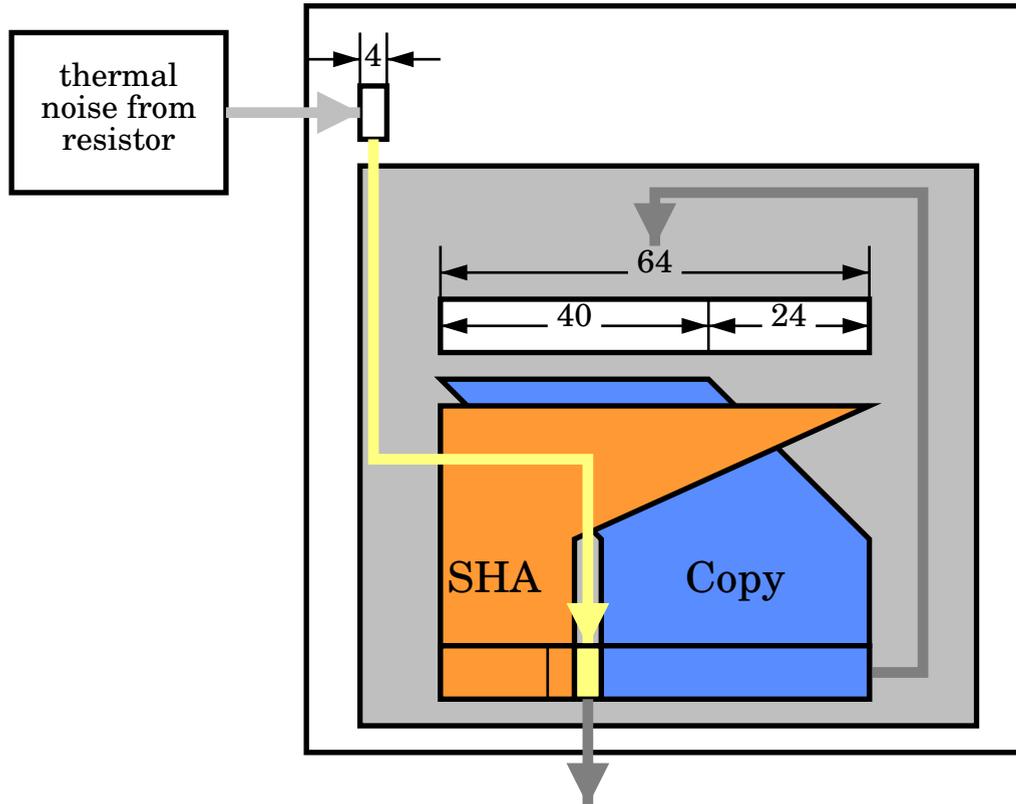

A RNG is *practically strong* if it cannot be predicted *in practice*. There might be *theoretical* attacks on the generator, but if they are not also *practical*, they are disregarded.

An example of an attack that is theoretical but not practical is one where a bit could be predicted with probability  $0.5 + 2^{-128}$ .

Remember, a generator is said to be *broken* if we can predict what a bit in the generator will be with probability  $0.5 + \epsilon$  for some  $\epsilon > 0$ .

# Is This a Good Generator?

# Requirements and Limitations (1)

---

The generator *must not* use only one source of randomness:

---

```
#include <unistd.h>

extern void* pgpRandomPool;

void
sample_dev_random() {
    int fd = open("/dev/random", O_RDONLY);
    char randBuf;

    /* ... */
    randBuf = read(fd, &randBuf, 1);
    pgpRandomAddBytes(&pgpRandomPool, &randBuf, 1);
    /* ... */
}
```

10

# Requirements and Limitations (1)

---

The generator *must not* use only one source of randomness:

---

```
#include <unistd.h>

extern void* pgpRandomPool;

void
sample_dev_random() {
    int fd = open("/dev/random", O_RDONLY);
    char randBuf;

    /* ... */
    randBuf = read(fd, &randBuf, 1);
    pgpRandomAddBytes(&pgpRandomPool, &randBuf, 1);
    /* ... */
}
```

10

---

This caused the “random” bytes to be added to consist exclusively of ‘0x01’ bytes.

# Requirements and Limitations (2)

---

5/71

Here is the proposed fix:

---

```
#include <unistd.h>

extern void* pgpRandomPool;

void
sample_dev_random() {
    int fd = open("/dev/random", O_RDONLY);
    char randBuf;

    /* ... */
    read(fd, &randBuf, 1);
    pgpRandomAddBytes(&pgpRandomPool, &randBuf, 1);
    /* ... */
}
```

10

## Requirements and Limitations (2)

---

Here is the proposed fix:

---

```
#include <unistd.h>

extern void* pgpRandomPool;

void
sample_dev_random() {
    int fd = open("/dev/random", O_RDONLY);
    char randBuf;

    /* ... */
    read(fd, &randBuf, 1);
    pgpRandomAddBytes(&pgpRandomPool, &randBuf, 1);
    /* ... */
}
```

10

---

The return code from *read(2)* isn't checked; therefore, nonrandom data could be added if the read fails.

## Requirements and Limitations (3) \_\_\_\_\_

The generator *should not* use hardware-specific methods to gather random data.

- Keystroke Timings.

## Requirements and Limitations (3)

---

The generator *should not* use hardware-specific methods to gather random data.

- Keystroke Timings. Often virtualized interfaces that don't let you get at the raw keystroke data (Windows) or network processing (remote logins);

## Requirements and Limitations (3)

---

The generator *should not* use hardware-specific methods to gather random data.

- Keystroke Timings. Often virtualized interfaces that don't let you get at the raw keystroke data (Windows) or network processing (remote logins);
- Some raw input methods may not exist on all operating systems, not even on all OS *types*: raw input on Unix system must be done using obscure *ioctl(2)* calls that aren't available everywhere;

## Requirements and Limitations (3)

---

The generator *should not* use hardware-specific methods to gather random data.

- Keystroke Timings. Often virtualized interfaces that don't let you get at the raw keystroke data (Windows) or network processing (remote logins);
- Some raw input methods may not exist on all operating systems, not even on all OS *types*: raw input on Unix system must be done using obscure *ioctl(2)* calls that aren't available everywhere;
- Even “direct” hardware access isn't: keystrokes are often processed through several processors before they arrive at the user process.

# *Requirements and Limitations (4)*

---

Mouse events aren't necessarily better:

# *Requirements and Limitations (4)*

---

7/71

Mouse events aren't necessarily better:

- Not all mouse events are human-generated: “Snap To” capability of some mouse drivers can position the mouse without human intervention.

# Requirements and Limitations (4)

---

7/71

Mouse events aren't necessarily better:

- Not all mouse events are human-generated: “Snap To” capability of some mouse drivers can position the mouse without human intervention.
- Networked applications transmit information about mouse events (usually in the clear), which makes the “random” (and secret) information publicly available.

# Requirements and Limitations (4)

---

Mouse events aren't necessarily better:

- Not all mouse events are human-generated: “Snap To” capability of some mouse drivers can position the mouse without human intervention.
- Networked applications transmit information about mouse events (usually in the clear), which makes the “random” (and secret) information publicly available.
- Networked applications might collapse multiple mouse events into one to save bandwidth, making mouse-wiggling less random than it should (or could) be.

# Further Requirements

---

- Resistant to **analysis of its input data.**
- Resistant to **manipulation of its input data.**
- Resistant to **analysis of its output data.**
- Resistant to **attempts at state recovery.**
- Make explicit any actions so that **conformance of code and design can be easily checked.**
- Ensure that the **internal state never leaks to the outside world.**
- Ensure that the **initial randomness is good enough to generate good data.**
- Ensure that the generator **generates good numbers.**

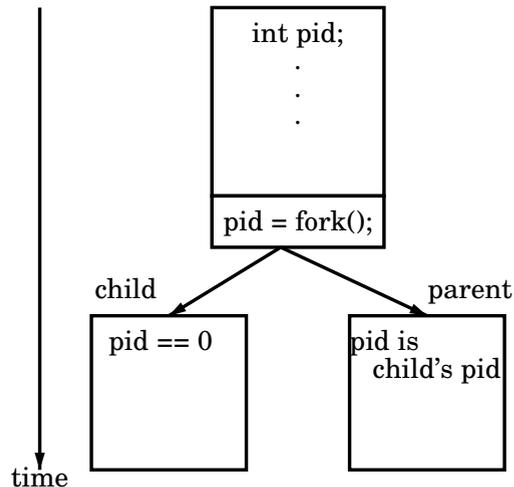

## Further Pitfalls: `fork(2)`

---

The `fork(2)` system call is the way in Unix to create new processes.

The `fork()` call makes a *copy* of the currently running process and then lets both run concurrently.

# Forking (2)

---

```
#include <sys/types.h>
#include <unistd.h>

void create_new_process() {
    pid_t pid;

    pid = fork();
    if (pid == -1) {
        /* Some error has happened */
    } else if (pid == 0) {
        /* Child code */
    } else {
        /* Parent code */
    }
}
```

10

---

The *fork(2)* system call returns *twice*: once in the parent and once in the child.

10/71

# *Why Is This A Problem?*

---

When a process forks, the operating system creates an exact copy of the parent and lets them both run concurrently (except for different return values of *fork(2)*).

# ***Why Is This A Problem?***

---

When a process forks, the operating system creates an exact copy of the parent and lets them both run concurrently (except for different return values of *fork(2)*).

Since the copy is exact, the random number generator state is copied along with everything else.

## *Why Is This A Problem?*

---

When a process forks, the operating system creates an exact copy of the parent and lets them both run concurrently (except for different return values of *fork(2)*).

Since the copy is exact, the random number generator state is copied along with everything else.

If the two processes run in parallel, the RNG will presumably generate related (if not identical) sequences of numbers.

## ***Why Is This A Problem?***

---

When a process forks, the operating system creates an exact copy of the parent and lets them both run concurrently (except for different return values of *fork(2)*).

Since the copy is exact, the random number generator state is copied along with everything else.

If the two processes run in parallel, the RNG will presumably generate related (if not identical) sequences of numbers.

That means that both processes will use the same cryptovariabes that are derived from the generator.

## Why Is This A Problem?

---

When a process forks, the operating system creates an exact copy of the parent and lets them both run concurrently (except for different return values of `fork(2)`).

Since the copy is exact, the random number generator state is copied along with everything else.

If the two processes run in parallel, the RNG will presumably generate related (if not identical) sequences of numbers.

That means that both processes will use the same cryptovariables that are derived from the generator.

And *that* is bad.

## Why Is This A Problem?

---

When a process forks, the operating system creates an exact copy of the parent and lets them both run concurrently (except for different return values of `fork(2)`).

Since the copy is exact, the random number generator state is copied along with everything else.

If the two processes run in parallel, the RNG will presumably generate related (if not identical) sequences of numbers.

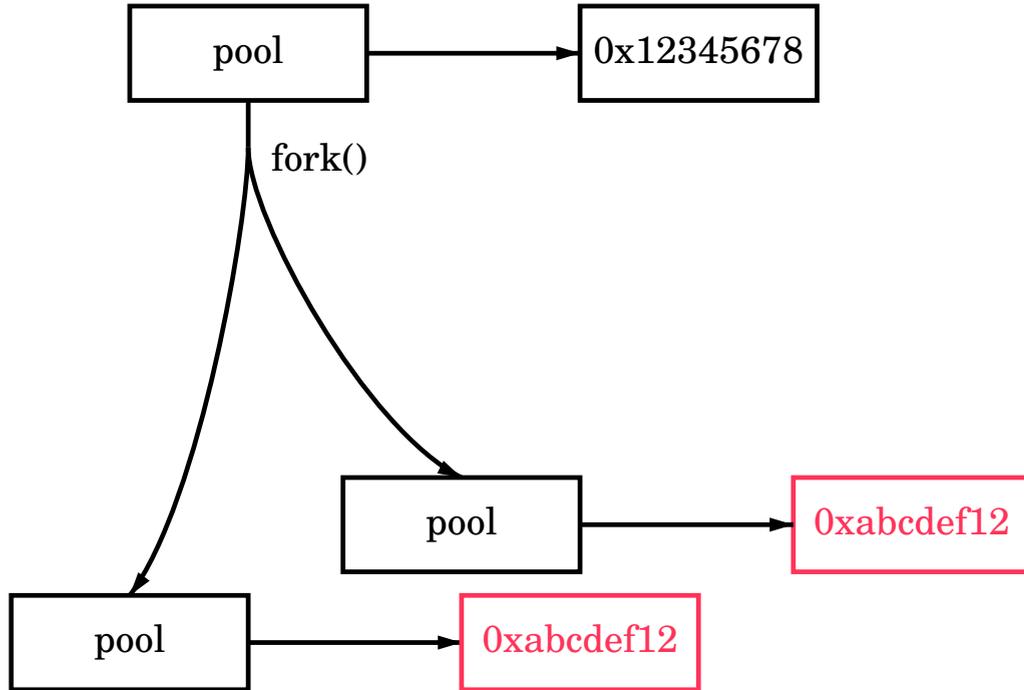

That means that both processes will use the same cryptovars that are derived from the generator.

And *that* is bad.

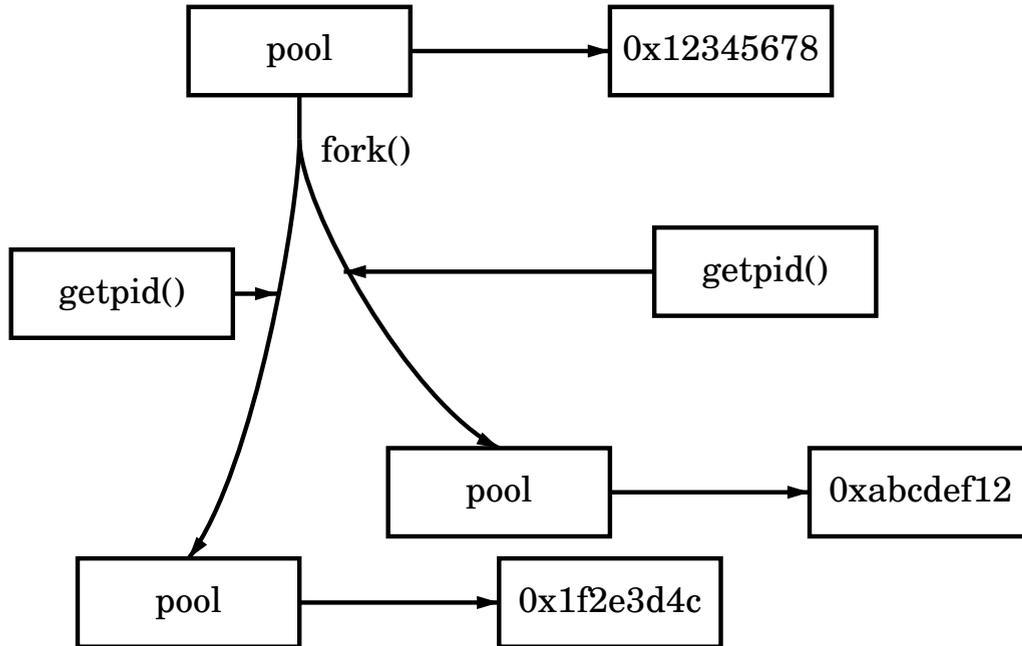

This problem is also difficult to avoid.

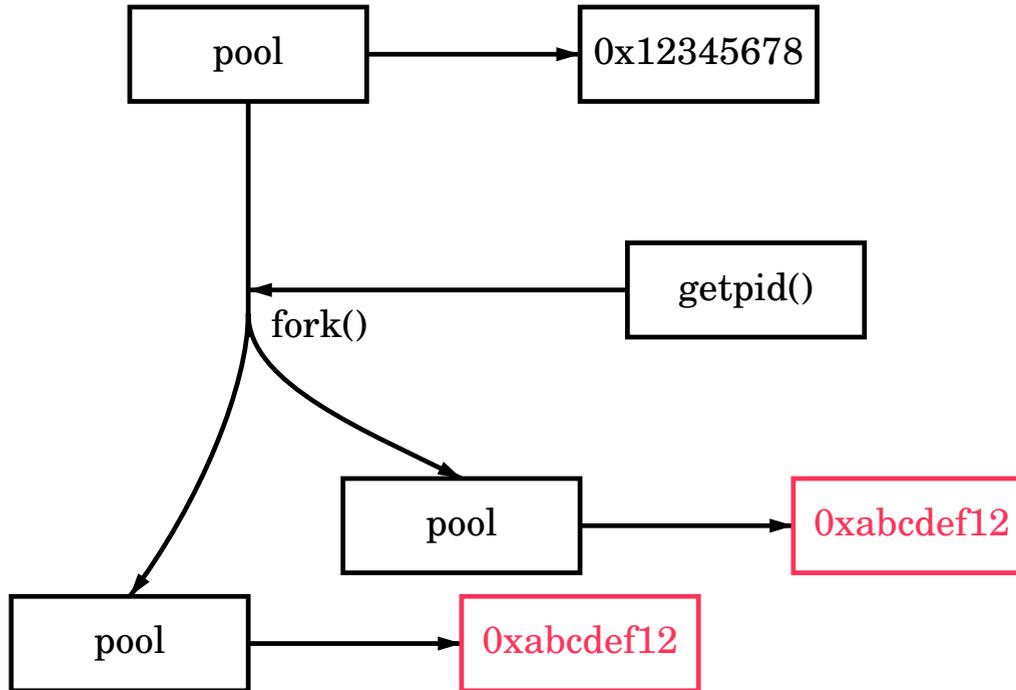

# Problem and Attempted Solution

# Problem and Attempted Solution

# Problem and Attempted Solution

# ***Solution***

---

1. Set *oldpid*  $\leftarrow$  *getpid()*.

## ***Solution***

---

1. Set  $oldpid \leftarrow getpid()$ .
2. Run the generator to generate output.

## Solution

---

1. Set  $oldpid \leftarrow getpid()$ .
2. Run the generator to generate output.
3. Set  $newpid \leftarrow getpid()$ . If  $oldpid = newpid$ , we haven't forked in the meantime, or this is the parent. Return the generator's output and terminate the algorithm.

## Solution

---

1. Set  $oldpid \leftarrow getpid()$ .
2. Run the generator to generate output.
3. Set  $newpid \leftarrow getpid()$ . If  $oldpid = newpid$ , we haven't forked in the meantime, or this is the parent. Return the generator's output and terminate the algorithm.
4. (At this point,  $oldpid \neq newpid$ , so we must have forked in the meantime, and this is the child process.) Return to step 1.

## Solution

---

1. Set  $oldpid \leftarrow getpid()$ .
2. Run the generator to generate output.
3. Set  $newpid \leftarrow getpid()$ . If  $oldpid = newpid$ , we haven't forked in the meantime, or this is the parent. Return the generator's output and terminate the algorithm.
4. (At this point,  $oldpid \neq newpid$ , so we must have forked in the meantime, and this is the child process.) Return to step 1.

This looks somewhat like two-phase-commit (because the technique was inspired by it).

# *Message Digest Ciphers*

# *Message Digest Ciphers*

---

A Message Digest Cipher turns a hash algorithm, such as MD5 or SHA, into a cipher.

They were invented in 1992 by Peter Gutmann and first analyzed by Stephan Neuhaus :-)

These ciphers are much faster than traditional block ciphers and are ideally suited to mix large amounts of data when the mixing process should not be reversible by an outsider.

## Recap: Hash Functions

---

$\{0, 1\}^k$  is the set of all bit strings of length  $k$ ;  $\{0, 1\}^*$  is the set of all bit strings, including the empty string. Any message can be viewed as a bit string by means of a suitable encoding.

Hash functions have the form  $h: \{0, 1\}^* \rightarrow \{0, 1\}^k$ , for some fixed  $k$ , and we call  $h(M)$  the *hash* of  $M$ .

A secure one-way hash function is a hash function with the following properties:

1. For each message  $M$ , it is easy to compute  $h(M)$ .
2. Given  $M$ , it is computationally infeasible to compute  $M'$  with  $h(M) = h(M')$  (secure against forgery).
3. It is computationally infeasible to compute  $M$  and  $M'$  with  $h(M) = h(M')$  (secure against collisions).

# *Incremental Hash Functions*

---

At least some of the time, the data one wants to hash isn't available all at once. Therefore, most hash functions allow one to hash *incrementally*.

# Incremental Hash Functions

---

At least some of the time, the data one wants to hash isn't available all at once. Therefore, most hash functions allow one to hash *incrementally*.

The definition of a hash function then becomes

$h: \{0, 1\}^k \times \{0, 1\}^* \rightarrow \{0, 1\}^k$ , and the hashing process takes a message  $M$ , splits into chunks  $(M_1, \dots, M_n)$  and computes the hash of  $M$  as  $h(h(h(\dots h(IV, M_1), \dots), M_{n-1}), M_n)$ , or

$$\begin{aligned}h_1 &= h(IV, M_1); \\h_{j+1} &= h(h_j, M_j); \\h(M) &:= h_n.\end{aligned}$$

Hash functions carry *state* between invocations.

# Message Digest Ciphers

---

Let  $K$  be an arbitrarily long key, let  $M = (M_1, \dots, M_n)$  be a message, broken up into chunks of  $k$  bits, and let  $IV$  be an initialization vector. Then set

$$C_1 = M_1 \oplus h(IV, K)$$

$$C_j = M_j \oplus h(C_{j-1}, K) \quad \text{for } 1 < j \leq n.$$

The recipient easily recovers the plaintext by

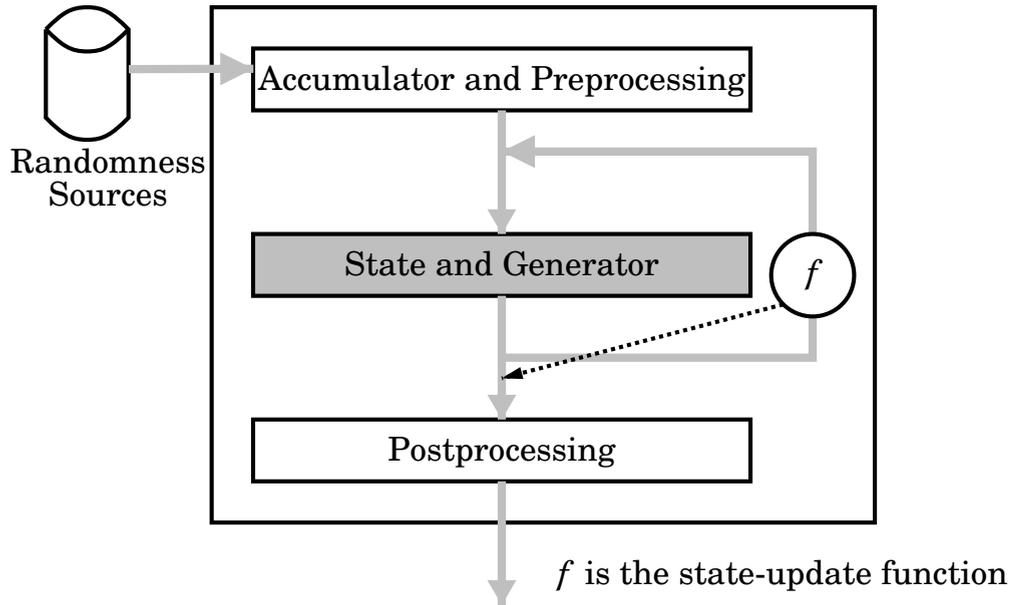

$$P_1 = C_1 \oplus h(IV, K)$$

$$P_j = C_j \oplus h(C_{j-1}, K) \quad \text{for } 1 < j \leq n.$$

This should be familiar: it's Cipher Feedback Mode.

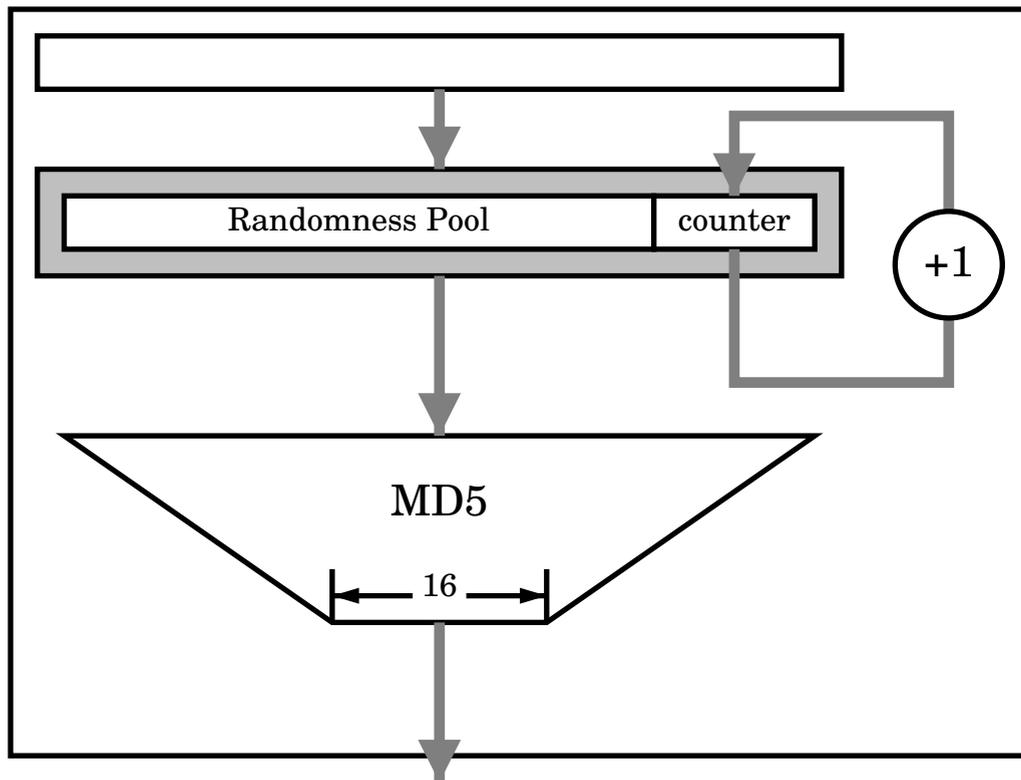

# A Model For RNGs

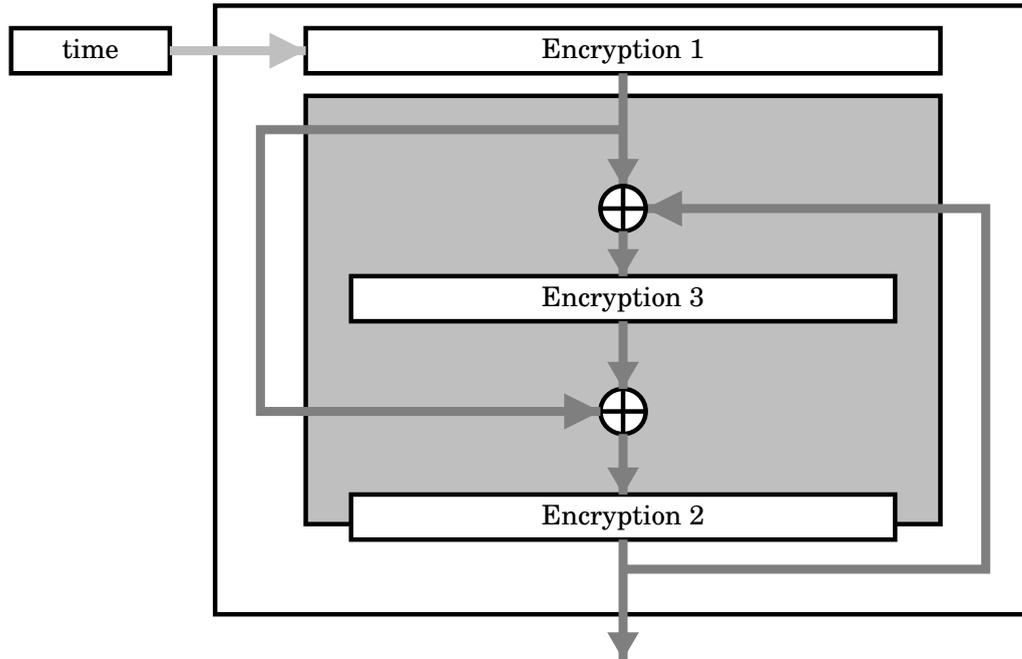

# Applied Cryptography

# ANSI X9.17

# PGP 2.x

# Curious PGP 2.x Implementation Bug

---

PGP 2.x contained the following function (paraphrased):

---

```
#include <stdlib.h>
```

```
/* Exclusive-or the contents of the SRC buffer into the DST buffer. */
```

```
void xor_buffers(void* dst, const void* src, size_t length) {
```

```
    unsigned char* dst_buffer = dst;
```

```
    const unsigned char* src_buffer = src;
```

```
    while (length--)
```

```
        *dst++ = *src++;
```

```
}
```

10

# PGP 2.x Implementation Fix

---

PGP 2.x *should have* contained the following function:

---

```
#include <stdlib.h>
```

```
/* Exclusive-or the contents of the SRC buffer into the DST buffer. */
```

```
void xor_buffers(void* dst, const void* src, size_t length) {
```

```
    unsigned char* dst_buffer = dst;
```

```
    const unsigned char* src_buffer = src;
```

```
    while (length--)
```

```
        *dst++ ^= *src++;
```

```
}
```

10

3. You *run the tests and compute a statistic*. For example, you compute the number of 0 bits in a sample of 20,000 bits.
4. You *compute the probability that the statistic has this value* (or is higher, or lower) *if the null hypothesis is true*. If this probability is less than  $p$ , we *reject the null hypothesis*.

# More About Tests

---

- You never *accept* the null hypothesis; you only ever *not reject* it.

60/71

## More About Tests

---

- You never *accept* the null hypothesis; you only ever *not reject* it.
- In practice, you'll conduct the test first and then later choose the lowest  $p$  that will not cause your null hypothesis to be rejected. Therefore, if you see a study that claims that “the data could not be rejected at the 5% level”, you can be sure that it *could have been* rejected at a 4% level.

- If you see nonstandard levels (i.e., everything but 10%, 5% or 1%), beware. This is a sure sign of trying to look good.
- A null hypothesis that can only not be rejected at the 10% level isn't doing particularly well. Insist on 5% or better.

- A null hypothesis that can only not be rejected at the 10% level isn't doing particularly well. Insist on 5% or better.
- A statistical dependency is not a cause-effect chain!

## Yet More About Tests

---

- In general, the statistic that you compute will be some measure of the sample's deviation from the ideal. For example, if you count the number  $k$  of 0 bits in a sample of  $n$  bits, the statistic could be  $0.5n - k$

## Yet More About Tests

---

- In general, the statistic that you compute will be some measure of the sample's deviation from the ideal. For example, if you count the number  $k$  of 0 bits in a sample of  $n$  bits, the statistic could be  $0.5n - k$  or  $|0.5n - k|$

## Yet More About Tests

---

- In general, the statistic that you compute will be some measure of the sample's deviation from the ideal. For example, if you count the number  $k$  of 0 bits in a sample of  $n$  bits, the statistic could be  $0.5n - k$  or  $|0.5n - k|$  or  $(0.5n - k)^2$

## Yet More About Tests

---

- In general, the statistic that you compute will be some measure of the sample's deviation from the ideal. For example, if you count the number  $k$  of 0 bits in a sample of  $n$  bits, the statistic could be  $0.5n - k$  or  $|0.5n - k|$  or  $(0.5n - k)^2$  or even  $(0.5n - k)^2 / 0.5n$  (the  $\chi^2$  statistic for this case).

## Yet More About Tests

---

- In general, the statistic that you compute will be some measure of the sample's deviation from the ideal. For example, if you count the number  $k$  of 0 bits in a sample of  $n$  bits, the statistic could be  $0.5n - k$  or  $|0.5n - k|$  or  $(0.5n - k)^2$  or even  $(0.5n - k)^2/0.5n$  (the  $\chi^2$  statistic for this case).
- That means that generally, large values of the statistic signify large deviations from the distribution that would occur if the null hypothesis were true.

## Yet More About Tests

---

- In general, the statistic that you compute will be some measure of the sample's deviation from the ideal. For example, if you count the number  $k$  of 0 bits in a sample of  $n$  bits, the statistic could be  $0.5n - k$  or  $|0.5n - k|$  or  $(0.5n - k)^2$  or even  $(0.5n - k)^2 / 0.5n$  (the  $\chi^2$  statistic for this case).
- That means that generally, large values of the statistic signify large deviations from the distribution that would occur if the null hypothesis were true.
- Therefore, most tables of statistics are computed to answer the question, “what is the probability of the statistic being this high, or higher, if the null hypothesis is in fact true?”

# *Tests for RNGs*

---

In order to use the generated numbers with any degree of confidence, you must test them

# *Tests for RNGs*

---

In order to use the generated numbers with any degree of confidence, you must test them, either beforehand or (much better) during operation.

## *Tests for RNGs*

---

In order to use the generated numbers with any degree of confidence, you must test them, either beforehand or (much better) during operation.

The National Institute of Standards (NIST) used to have in its Federal Information Processing Standard (FIPS) 140 a number of test procedures for random number generators, but these have been removed in the newer version of the document.

## *Tests for RNGs*

---

- the runs test; and
- the long runs test.

## *The Monobit Test*

---

“A single bit stream of 20,000 consecutive bits of output from each RNG shall be subjected to the following four tests: [. . .]. Count the number of ones in the 20,000 bit stream. Denote this quantity by  $X$ . The test is passed if  $9,725 \leq X \leq 10,275$ .”

## *The Monobit Test*

---

“A single bit stream of 20,000 consecutive bits of output from each RNG shall be subjected to the following four tests: [. . .]. Count the number of ones in the 20,000 bit stream. Denote this quantity by  $X$ . The test is passed if  $9,725 \leq X \leq 10,275$ .”

Where do these magic numbers (20,000, 9,725, and 10,275) come from?

# *The Monobit Test*

---

Where do these magic numbers (20,000, 9,725, and 10,275) come from?

What is the confidence level for this test?

One thing is immediately obvious: the 20,000 comes from the desire to have a meaningful test (so that the number of bits sampled must not be too low), that is yet practical to carry out (so that the number of bits sampled must not be too high).

# *The Chi-Square Test*

---

When experiment outcomes fall naturally into  $K$  discrete categories (such as 0 and 1 bits), the chi-square (or  $\chi^2$ ) test is the test of choice.

# *The Chi-Square Test*

---

When experiment outcomes fall naturally into  $K$  discrete categories (such as 0 and 1 bits), the chi-square (or  $\chi^2$ ) test is the test of choice.

If the outcome is a real number (such as the length of a rod) or if  $K$  is very large (such as the lifetime of a light bulb in seconds), the  $\chi^2$  test can (should) not be used.

# The Chi-Square Test

---

When experiment outcomes fall naturally into  $K$  discrete categories (such as 0 and 1 bits), the chi-square (or  $\chi^2$ ) test is the test of choice.

If the outcome is a real number (such as the length of a rod) or if  $K$  is very large (such as the lifetime of a light bulb in seconds), the  $\chi^2$  test can (should) not be used.

We make  $n$  *independent* experiments and compute  $Y_k$ , the number of experiments that fell into category  $k$  ( $1 \leq k \leq K$ ).

# The Chi-Square Test

---

When experiment outcomes fall naturally into  $K$  discrete categories (such as 0 and 1 bits), the chi-square (or  $\chi^2$ ) test is the test of choice.

If the outcome is a real number (such as the length of a rod) or if  $K$  is very large (such as the lifetime of a light bulb in seconds), the  $\chi^2$  test can (should) not be used.

We make  $n$  *independent* experiments and compute  $Y_k$ , the number of experiments that fell into category  $k$  ( $1 \leq k \leq K$ ).

If each experiment has probability  $p_k$  to end up in category  $k$  if the null hypothesis is true, then the  $\chi^2$  test computes

$$\chi^2 = \sum_{k=0}^K \frac{(Y_k - np_k)^2}{np_k}.$$

# *Chi-Square Distribution*

---

What's the probability that the  $\chi^2$  statistic should be as large as it is, or larger, if the null hypothesis is true?

# Chi-Square Distribution

---

What's the probability that the  $\chi^2$  statistic should be as large as it is, or larger, if the null hypothesis is true?

$$Q(\chi^2, d) = 1 - \frac{\gamma(d/2, \chi^2/2)}{\Gamma(d/2)},$$

where  $d$  is the *number of degrees of freedom*, which is in our case equal to  $K - 1$

# Chi-Square Distribution

---

What's the probability that the  $\chi^2$  statistic should be as large as it is, or larger, if the null hypothesis is true?

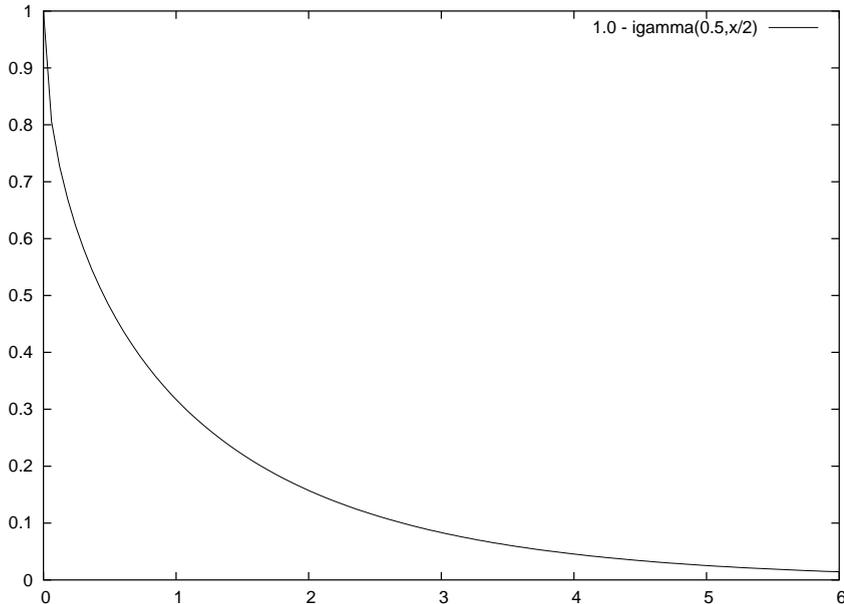

$$Q(\chi^2, d) = 1 - \frac{\gamma(d/2, \chi^2/2)}{\Gamma(d/2)},$$

where  $d$  is the *number of degrees of freedom*, which is in our case equal to  $K - 1$ , and  $\gamma(a, x)$  and  $\Gamma(x)$  are the incomplete gamma function and the gamma function defined by

$$\begin{aligned} \gamma(a, x) &= \int_0^x e^{-t} t^{a-1} dt && \text{for } a > 0; \text{ and} \\ \Gamma(x) &= \int_0^\infty e^{-t} t^{x-1} dt && \text{for } x \neq 0, -1, -2, \dots \end{aligned}$$

# Chi-Square For One Degree of Freedom

(Note that gnuplot defines  $igamma(a, x) = \gamma(a, x)/\Gamma(a)$  and calls *that* the incomplete gamma function.)

## What About the Monobit Test?

---

The monobit test is a  $\chi^2$  test in disguise. We set  $n = 20,000$  and  $K = 2$  and call the number of 1 bits  $N$ . We have  $p_1 = p_2 = 0.5$ . Then the  $\chi^2$  statistic for  $N = 10275$  (or  $N = 9725$ ) is

$$\begin{aligned}\chi^2 &= ((n - N) - np_1)^2 / np_1 + (N - np_2)^2 / np_2 \\ &= \frac{((20,000 - 10,275) - 10,000)^2}{10,000} + \frac{(10,275 - 10,000)^2}{10,000} \\ &= ((10,000 - 10,275)^2 + (10,275 - 10,000)^2) / 10,000 \\ &= 275^2 / 5,000 \\ &= 15.125,\end{aligned}$$

and  $Q(15.125, 1) \approx 10^{-4}$  (to nearly three significant digits).

## *Okay, What About It?* \_\_\_\_\_

That means that a deviation of more than 275 from the expected 10,000 one bits will occur only about one time in ten thousand in a generator whose bits are really equidistributed.

## *Okay, What About It?* \_\_\_\_\_

That means that a deviation of more than 275 from the expected 10,000 one bits will occur only about one time in ten thousand in a generator whose bits are really equidistributed.

So the monobit test is like a  $\chi^2$  test with a confidence level of  $10^{-4}$ .

## Okay, What About It? \_\_\_\_\_

That means that a deviation of more than 275 from the expected 10,000 one bits will occur only about one time in ten thousand in a generator whose bits are really equidistributed.

So the monobit test is like a  $\chi^2$  test with a confidence level of  $10^{-4}$ .

Sounds impressive.

## Okay, What About It? \_\_\_\_\_

That means that a deviation of more than 275 from the expected 10,000 one bits will occur only about one time in ten thousand in a generator whose bits are really equidistributed.

So the monobit test is like a  $\chi^2$  test with a confidence level of  $10^{-4}$ .

Sounds impressive. Does this mean that this is a particularly good test?

No, because “equidistributed” does not mean “random”. For example, the generator that alternately outputs 0 and 1 bits will pass this test every time, even though its output isn’t particularly random.

## Okay, What About It?

So the monobit test is like a  $\chi^2$  test with a confidence level of  $10^{-4}$ .

Sounds impressive. Does this mean that this is a particularly good test?

No, because “equidistributed” does not mean “random”. For example, the generator that alternately outputs 0 and 1 bits will pass this test every time, even though its output isn’t particularly random.

Good LCPRNGs will also pass this test every time, even though they are trivially broken.

# *What Does That Mean?*

---

That means that we cannot rely on one test alone, but must instead run a battery of tests, just like FIPS 140 does.

# *What Does That Mean?*

---

That means that we cannot rely on one test alone, but must instead run a battery of tests, just like FIPS 140 does.

Or (better) the DIEHARD tests by George Marsaglia (see References).

## ***What Does That Mean?*** \_\_\_\_\_

That means that we cannot rely on one test alone, but must instead run a battery of tests, just like FIPS 140 does.

Or (better) the DIEHARD tests by George Marsaglia (see References).

We must also try to break the *design* of the generator, something that no statistical test can do for us.
